**Abstract.** We report on the investigation of the spatial distribution of the flickering sources in the dwarf nova V2051 Oph with eclipse mapping techniques. Low-frequency flickering originates in the gas stream and is related to the mass transfer process, whereas high-frequency flickering arises in the accretion disk and is probably connected to magneto-hydrodynamic turbulence.

V2051 Oph is distinguished among other eclipsing dwarf nova by its remarkable flickering activity (amplitude  $\gtrsim 30$  per cent). The large flickering amplitude and short orbital period make this binary an ideal target for flickering studies with eclipse mapping techniques.

Time-series of CCD photometry of V2051 Oph in the B-band were obtained at the Laboratório Nacional de Astrofísica (Brazil), from 1998 to 2002, while the star was in quiescence. The data comprise 36 eclipse light curves obtained with the same instrument and telescope, which ensures a high degree of uniformity to the data set. The data can be grouped in two different brightness levels, named the 'faint' and 'bright' states. The differences in brightness are caused by long-term variations in the mass transfer rate from the secondary star. The white dwarf is hardly affected by the long-term changes. Its flux increases by only 10 per cent from the faint to the bright state, whereas the disk flux raises by a factor of 2.

We applied the 'single' and 'ensemble' methods (see Bruch 2000) to the set of light curves of V2051 Oph to derive the orbital dependency of its steady-light, long-term brightness changes, low- and high-frequency flickering components. The 'ensemble' method samples flickering at all frequencies. But because the power spectrum density of the flickering is well described by a power-law  $P(f) \propto f^{-\alpha}$ , an ensemble curve is dominated by the low-frequency flickering components. On the other hand, the 'single' method produces curves which sample the high-frequency flickering. Thus, the combination of both methods opens the possibility not only to probe the location of the flickering sources but also to separate low- and high-frequency components of the flickering.

Eclipse maps of the steady-light show asymmetric brightness distributions with enhanced emission along the ballistic stream trajectory, in a clear evidence of gas stream overflow. The comparison between the steady-light maps of the faint and bright states suggests that the quiescent disk of V2051 Oph responds to changes in mass transfer rate in an homologous way.

Our flickering mapping analysis reveal the existence of two different sources of flickering in V2051 Oph, which lead to variability at distinct frequencies. The low-frequency flickering arises mainly in the overflowing gas stream and is connected to the mass transfer process. Its maximum emission occurs at the

position of closest approach of the gas stream to the white dwarf, and its spatial distribution changes in response to variations in mass transfer rate. In the bright state there is additional contribution from an uneclipsed component of 8 per cent of the total flux, which may indicate the development of a vertically-extended clumpy or turbulent wind from the inner disk regions. Unsteady mass transfer or turbulence generated after the shock between the stream and the disk material may be responsible for this stream flickering component.

The high-frequency flickering is produced in the accretion disk. It is spread over the disk surface with a radial distribution similar to that of the steady-light maps and it shows no evidence of emission from the hot spot, gas stream or white dwarf. This disk flickering component has a relative amplitude of about 3 per cent of the steady-light, independent of disk radius and brightness state. If the disk flickering is caused by fluctuations in the energy dissipation rate induced by MHD turbulence (Geertsema & Achterberg 1992), its relative amplitude lead to a viscosity parameter  $\alpha_{cool} = 0.1 - 0.2$  at all radii for the quiescent disk of V2051 Oph (Baptista & Bortoletto 2004). This is comparable to the inferred viscosity in outburst  $\alpha_{hot} \simeq 0.14$  (Santos, Baptista & Faundez-Abans 2004) – in contradiction with a fundamental prediction of the disk instability model (namely,  $\alpha_{hot} \gtrsim 5 \alpha_{cool}$ ).

Previous studies suggested that flickering may originate from two separate sources, the hot spot and a turbulent inner disk region (Warner 1995; Bruch 2000). Our flickering mapping experiment reveals a more complex situation, in which flickering arising from the inner disk regions may in fact have the same origin as the hot spot flickering, namely, the mass transfer process. Stream flickering from the inner disk regions may be largely dominant over the disk flickering if gas stream overflow occurs in a quiescent dwarf novae, because the contribution from the disk flickering in this case is small (since the disk itself is relatively faint). Also, although the hot spot contributes to the flickering, it is a minor source in comparison to the inner gas stream in this situation. This seems to be the case in V2051 Oph. On the other hand, if the disk flickering amplitude is a fixed fraction of the steady disk light, it might become the dominant flickering source and may appear as arising mainly from the innermost disk regions in a high mass transfer, nova-like system as the surface brightness of the bright, opaque disks of these systems decreases sharply with radius.

Finally, we note that the measurement of the disk flickering component yields a novel and independent way to estimate the disk viscosity parameter  $\alpha$ . The large value found in this first experiment seems to favor the mass-transfer instability model (see Warner 1995).
